A 2-hour oral glucose tolerance test result $\geq 11.1$ mmol/L predicted all-cause mortality better than a fasting glucose level $\geq 7.0$ mmol/L

**Question**

What is the relative accuracy of fasting plasma glucose (FPG) levels alone (American Diabetes Association [ADA] diagnostic criteria for diabetes mellitus) compared with 2-hour glucose levels (World Health Organization [WHO] criteria) for predicting the risk for mortality associated with diabetes?

**Design**

Comparison of the ADA and WHO diagnostic criteria for diabetes for predicting all-cause mortality (the Diabetes Epidemiology: Collaborative Analysis of Diagnostic Criteria in Europe [DECODE] study).

**Setting**

13 centers in Europe.

**Participants**

18,048 men and 7,316 women $\geq$ 30 years of age who had had baseline FPG levels and standard 2-hour oral glucose tolerance test (OGTT) results recorded and who were part of 13 European cohort studies. Follow-up was a median of 7.3 years.

**Description of tests and diagnostic standard**

Diagnostic tests were 2 different criteria for diabetes: the ADA criteria (FPG level $\geq 11.1$ mmol/L for capillary or whole-blood samples) and the 2-hour WHO criteria (glucose level after the 2-h 75 g OGTT $\geq 11.1$ mmol/L for plasma and capillary blood samples or $\geq 10.0$ mmol/L for whole-blood samples). All-cause mortality was used as the diagnostic standard.

**Main outcome measures**

Hazard ratios (HRs) for all-cause mortality based on the 2 glucose criteria.

**Main results**

HRs for all-cause mortality, adjusted for age, sex, and center, were calculated for the different glucose cut points based on the ADA and WHO diagnostic criteria for diabetes and glucose intolerance. HRs were also compared with persons who had normal FPG ($< 6.1$ mmol/L) or normal 2-hour glucose levels ($< 7.8$ mmol/L) (Table). FPG levels did not predict mortality after adjustment for the 2-hour glucose level.

**Conclusion**

Both a fasting plasma glucose level $\geq 7.0$ mmol/L and a 2-hour glucose level $\geq 11.1$ mmol/L predicted all-cause mortality.

**Commentary**

This European study examined the relation between glucose tolerance and mortality. The results support 2 conclusions: The new ADA criteria for diabetes based on FPG levels alone underestimate the risk for long-term mortality more than the WHO criteria, which are based on glucose levels after the 2-hour 75 g OGTT. The new ADA criteria for impaired fasting glucose levels (FPG 6.1 to 6.9 mmol/L) underestimate the risk for mortality more than the ADA or WHO criteria for impaired glucose tolerance (OGTT 7.8 to 11.1 mmol/L). Similar conclusions have been drawn in recent studies (1, 2). In the Cardiovascular Health Study of 4515 persons $> 65$ years of age, 22% had diabetes and impaired fasting glucose according to the ADA criteria, and 47% had diabetes and impaired glucose tolerance according to the WHO criteria (2). Therefore, the ADA criteria to determine impaired fasting glucose level have low sensitivity for predicting diabetes and cardiovascular mortality. A subgroup analysis of the DECODE study in older men and women suggests that a third of persons with undiagnosed diabetes have 2-hour glucose levels $\geq 11.1$ mmol/L, and half of these have FPG levels $< 7.0$ mmol/L (3).

A recent meta-analysis suggested that a 2-hour glucose level $> 7.8$ mmol/L was a better determinant of cardiovascular events than FPG levels $> 6.1$ mmol/L (4).

Increasing evidence suggests an association between impaired glucose tolerance and cardiovascular disease or mortality even in the absence of fasting hyperglycemia. Patients who have an impaired fasting glucose level should be further assessed by a 2-hour glucose challenge test as well as for other cardiovascular risk factors.
